

# Arrays, Vectors

## Searching, Sorting

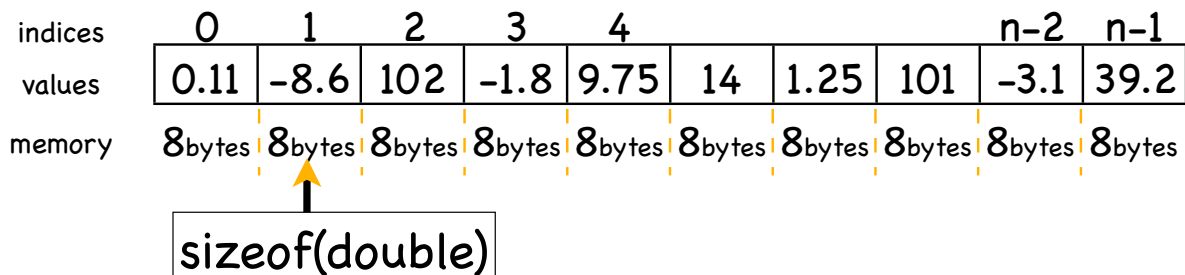

## Arrays

---

- ④ `char s[200]; //array of 200 characters`
  - different type than class `string`
- ④ can be accessed as `s[0], s[1], ..., s[199]`
  - `s[0]='H'; s[1]='e'; s[2]='l'; s[3]='l'; s[4]='o';`
  - `char a = s[3];`
- ④ works for any type
  - `double d[10]; int i[100];`
- ④ C++ does not check for array bounds !!

# Memory allocation for arrays

---

# Array initialization

---

## complete

- `int A[5] = {0, 1, 10, 100, 1000}`

## partial

- `int A[5] = {0, 1, 10}` // allocates `int[5]`
- only indices 0, 1, 2 are initialized with values

## implicit size

- `int A[] = {0, 1, -1, 2}` // allocates an `int[4]`

# Arrays input to function

---

- ☉ Act as reference variable : changes made are reflected to the call array
  - in fact, it is a reference variable
  - unless defined with const
- ☉ `int function (int A[10], double x)`
- ☉ `int function (int A[], double x)`
- ☉ `int function (const int A[], double x)`
- ☉ `int function (int A[], int array_size, double x)`

# Partially filled arrays

---

- ☉ similar to a stack
  - but in here we can use any element, not only the top
- ☉ `int A[10] = {3, -1, 3, 41, 90}`
- ☉ `int current_size = 5;`
- ☉ the current-top can move up or down
- ☉ example: Tower of Hanoi

declared, not currently used

current top

	?
	?
	?
	35
	120
2	43
1	-1
0	10

# Array copy

---

- ⊗ `int A[5] = {1,2,3,4,5}`
- ⊗ `int B[5]; B=A; //error`
- ⊗ instead copy each element
  - `for (int i=0;i<5;i++) B[i] = A[i];`

# Parallel arrays (DB tables)

---

ID	NAME	ID	AGE	ID	GENDER	ID	School Status
0	Virgil	0	34	0	M	0	PhD
1	Alex	1	22	1	F	1	in College
2	Bob	2	18	2	M	2	HighSchool
3	Cindy	3	31	3	F	3	PhD Candidate
4		4		4		4	
n		n		n		n	

- ⊗ requires "join" operations

# Array bounds

---

- ⊖ C++ does not check for array bounds !!
- ⊖ very easy to read/write at the wrong location memory address
  - writing particularly bad : can overwrite a variable

Searching  
Sorting

# Brute force/linear search

---

- ⌚ Linear search: look through all values of the array until the desired value/event/condition found
- ⌚ Running Time: linear in the number of elements, call it  $O(n)$
- ⌚ Advantage: in most situations, array does not have to be sorted

# Binary Search

---

- ⌚ Array must be sorted
- ⌚ Search array  $A$  from index  $b$  to index  $e$  for value  $V$
- ⌚ Look for value  $V$  in the middle index  $m = (b+e)/2$ 
  - That is compare  $V$  with  $A[m]$ ; if equal return index  $m$
  - If  $V < A[m]$  search the second half of the array
  - If  $V > A[m]$  search the first half of the array

	$b$				$m$				$e$	
$V=3$	-4	-1	0	0	1	1	3	19	29	47

$A[m]=1 < V=3 \Rightarrow$  search moves to the right half

# Binary Search Efficiency

---

- every iteration/recursion
  - ends the procedure if value is found
  - if not, reduces the problem size (search space) by half
- worst case : value is not found until problem size=1
  - how many reductions have been done?
  - $n / 2 / 2 / 2 / \dots / 2 = 1$ . How many 2-s do I need ?
  - if  $k$  2-s, then  $n = 2^k$ , so  $k$  is about  $\log(n)$
  - worst running time is  $O(\log n)$

## Search: tree of comparisons

---

- tree of comparisons : essentially what the algorithm does

# Search: tree of comparisons

---

- tree of comparisons : essentially what the algorithm does
  - each program execution follows a certain path

# Search: tree of comparisons

---

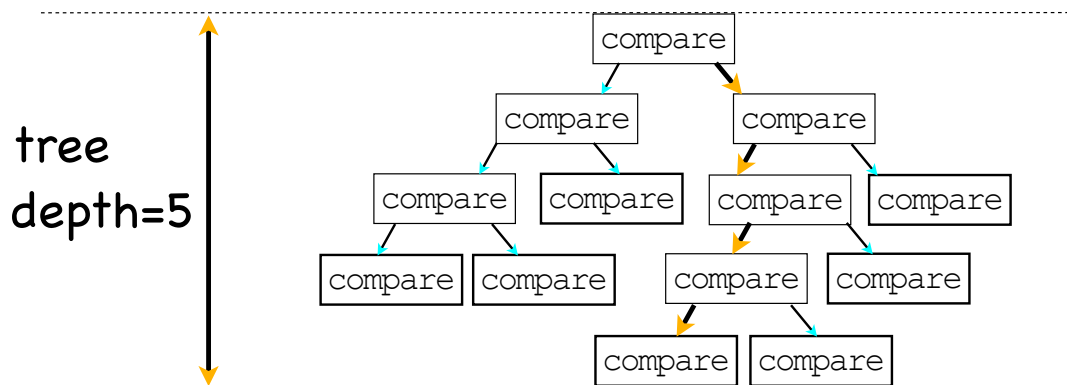

- tree of comparisons : essentially what the algorithm does
  - each program execution follows a certain path
  - red nodes are terminal / output
  - the algorithm has to have at least n output nodes... why?

# Search: tree of comparisons

- ⊗ tree of comparisons : essentially what the algorithm does
  - each program execution follows a certain path
  - red nodes are terminal / output
  - the algorithm has to have  $n$  output nodes... why ?
  - if tree is balanced, longest path = tree depth =  $\log(n)$
  - if tree not balanced, path can be longer

# Bubble Sort

- ⊗ Simple idea: as long as there is an inversion, swap the bubble
  - inversion = a pair of indices  $i < j$  with  $A[i] > A[j]$
  - swap  $A[i] \leftrightarrow A[j]$ 
    - ⊗ directly swap  $(A[i], A[j]);$
    - ⊗ code it yourself:  $aux = A[i]; A[i]=A[j];A[j]=aux;$
- ⊗ how long does it take?
  - worst case : how many inversions have to be swapped?
  - $O(n^2)$

# Insertion Sort

---

- ⌚ partial array is sorted

1	5	8	20	49					
---	---	---	----	----	--	--	--	--	--

# QuickSort - pseudocode

- ☉ QuickSort( $A, b, e$ ) //array  $A$ , sort between indices  $b$  and  $e$

- $q = \text{Partition}(A, b, e)$  //returns pivot  $q$ ,  $b \leq q \leq e$
- //Partition also rearranges  $A$  so that if  $i < q$  then  $A[i] \leq A[q]$
- // and if  $i > q$  then  $A[i] > A[q]$
- if ( $b < q - 1$ ) QuickSort( $A, b, q - 1$ )
- if ( $q + 1 < e$ ) QuickSort( $A, q + 1, e$ )

- ☉ After Partition the pivot index contains the right value:

$b=0$

$q=3$

$e=9$

-3	0	5	7	18	8	7	29	21	10
----	---	---	---	----	---	---	----	----	----

# QuickSort Partition

- ③ TASK: rearrange  $A$  and find pivot  $q$ , such that
  - all elements before  $q$  are smaller than  $A[q]$
  - all elements after  $q$  are bigger than  $A[q]$
- ③ Partition ( $A, b, e$ )
  - $x=A[e]$  // pivot value
  - $i=b-1$
  - for  $j=b$  TO  $e-1$ 
    - if  $A[j] \leq x$  then
      - $i++$ ; swap  $A[i] \leftrightarrow A[j]$
  - swap  $A[i+1] \leftrightarrow A[e]$
  - $q=i+1$ ; return  $q$

## Partition Example

- ③ set pivot value  $x = A[e]$ , //  $x=4$ 
  - $i$  = index of last value  $< x$
  - $i+1$  = index of first value  $> x$
- ③ run  $j$  through array indices  $b$  to  $e-1$ 
  - if  $A[j] \leq x$  //see steps (d), (e)
    - swap ( $A[j], A[i+1]$ );
    - $i++$ ; //advance  $i$
- ③ move pivot in the right place
  - swap (pivot= $A[e]$ ,  $A[i+1]$ )
- ③ return pivot index
  - return  $i+1$

# QuickSort time

---

- ⦿ Depends on the Partition balance
- ⦿ Worst case: Partition produces unbalanced split  $n = (1, n-1)$  most of the time
  - results in  $O(n^2)$  running time
- ⦿ Average case: most of the time split balance is not worse than  $n = (cn, (1-c)n)$  for a fixed  $c$ 
  - for example  $c=0.99$  means balance not worse than  $(1/100*n, 99/100*n)$
  - results in  $O(n*\log(n))$  running time

# Merge two sorted arrays

---

- ⦿ two sorted arrays
  - $A[] = \{1, 5, 10, 100, 200, 300\}$ ;  $B[] = \{2, 5, 6, 10\}$ ;
- ⦿ merge them into a new array  $C$ 
  - index  $i$  for array  $A[]$ ,  $j$  for  $B[]$ ,  $k$  for  $C[]$
  - init  $i=j=k=0$ ;
  - while (what\_condition\_?)
    - ⦿ if  $(A[i] \leq B[j]) \{ C[k]=A[i], i++ \}$  //advance  $i$  in  $A$
    - ⦿ else  $\{C[k]=B[j], j++\}$  // advance  $j$  in  $B$
    - ⦿ advance  $k$
  - end\_while

# MergeSort

---

- ⦿ divide and conquer strategy
- ⦿ MergeSort array A
  - divide array A into two halves A-left, A-right
  - MergeSort A-left (recursive call)
  - MergeSort A-right (recursive call)
  - Merge (A-left, A-right) into a fully sorted array
- ⦿ running time :  $O(n*\log(n))$

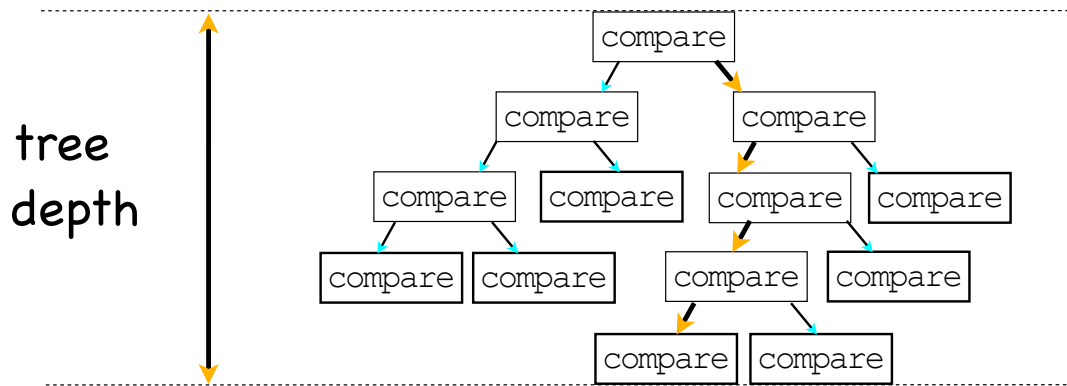

## Sorting : stable; in place

---

- ⦿ stable: preserve relative order of elements with same value
- ⦿ in place: dont use significant additional space (arrays)

	time	in-place	stable
Bubble	$n^2$	✓	✓
Insertion	$n^2$	✓	✓
Selection	$n^2$	✗	?
QuickSort	$n*\log(n)$	✓	?
MergeSort	$n*\log(n)$	✗	✓

# Sorting : tree of comparisons

- ④ tree of comparisons : essentially what the algorithm does
  - each program execution follows a certain path
  - red nodes are terminal / output
  - the algorithm has to have  $n!$  output nodes... why ?
  - if tree is balanced, longest path = tree depth =  $n \log(n)$
  - if tree not balanced, path can be longer

## Linear-time Sorting

- ④ Counting Sort ( $A[]$ ) : count values, NO comparisons
- ④ STEP 1 : build array C that counts A values
  - init  $C[] = 0$  ; run index i through A
    - ④ value =  $A[i]$
    - ④  $C[\text{value}] ++$ ; //counts each value occurrence
- ④ STEP 2: build array D of positions
  - init total = 0; run index i through C
    - ④  $D[i] = \text{total}$ ;
    - ④ total +=  $C[i]$ ;
- ④ STEP3: assign values to output array E
  - run index i through A
    - ④ value =  $A[i]$ ;
    - ④ position =  $D[i]$ ;
    - ④  $E[\text{position}] = \text{value}$ ;

# Two Dim Arrays, Vectors, Basic Hashing

## Two dimensional array = matrix

---

- `double M[10][20]; //matrix of real numbers`
- allocates  $10 \times 20 \times \text{sizeof}(\text{double}) = 1600$  bytes
- as function parameter: must specify the # of columns
  - `int myfunction (double X[][20], int rows)`
- `double M[2][5]; //allocates 80 bytes:`

indices	0 0	0 1	0 2	0 3	0 4	1 0	1 1	1 2	1 3	1 4
values	0.11	-8.6	102	-1.8	9.75	14	1.25	101	-3.1	39.2
memory	8bytes	8bytes	8bytes	8bytes	8bytes	8bytes	8bytes	8bytes	8bytes	8bytes

↑  
`sizeof(double)`

# Two dimensional array = matrix

---

- ⦿ `double C[10][20],B[10][20];`
- ⦿ `C = A + B; //error`
  - instead compute each element
    - ⦿ `for (int i=0; i<10; i++)`
    - ⦿ `for (int j=0; j<20; j++)`
      - ⦿ `C[i][j] = A[i][j] + B[i][j];`
- ⦿ `double D[20][5],E[10][5];`
- ⦿ `E = A*D; //error`
  - instead compute each element
    - ⦿ `for i (rows of A)`
    - ⦿ `for j (columns of D)`
      - ⦿ `C[i][j]=0;`
      - ⦿ `for k (columns of A)`
        - ⦿ `add component A(i,k)B(k,j) to C[i][j] ;`

# Matrix determinant

---

- ⦿ Recursive formula. Fix a row i:

$$|A| = \sum_{j=1}^m (-1)^{i+j} a_{ij} M_{ij}$$

- ⦿ where  $M_{ij}$  is the determinant of the matrix obtained from A by removing row i and column j

# Matrix determinant

- Recursive formula. Fix a row  $i$ :

$$|A| = \sum_{j=1}^m (-1)^{i+j} a_{ij} M_{ij}$$

- where  $M_{ij}$  is the determinant of the matrix obtained from  $A$  by removing row  $i$  and column  $j$

$$i = 1 \quad \begin{array}{c} j = 1 \\ \left( \begin{array}{ccc} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{array} \right) \end{array} \quad \begin{array}{c} j = 2 \\ \left( \begin{array}{ccc} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{array} \right) \end{array} \quad \begin{array}{c} j = 3 \\ \left( \begin{array}{ccc} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{array} \right) \end{array}$$

For example, for a  $3 \times 3$  matrix, the above formula gives

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = a_{11} \begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} - a_{12} \begin{vmatrix} a_{21} & a_{23} \\ a_{31} & a_{33} \end{vmatrix} + a_{13} \begin{vmatrix} a_{21} & a_{22} \\ a_{31} & a_{32} \end{vmatrix} ;$$

# Vectors

- part of Standard Template Library (STL)
  - some compilers do not support it
  - some methods work differently on different compilers
- `#include <vector>`
- `vector <int> a; //initial size 1 int`
- `vector <int> b(10); //initial size 10 ints`
- `vector <int> c(10, 1); //initial size 10 ints all initialized with value 1`
- `vector <int> d(b); //initial size 10 ints, having the same content as vector b`
- vectors change size dynamically: they automatically allocate more memory when need it
  - `d[14]=1452; //this is still out of bounds`

# Vectors

---

- array syntax works
  - more options available
- `vector <double> x(20,0);`
- `x[2]=-90.67; x[4]=1.46; x[6]=0.66`
- `for (int i=0;i<x.size();i++)`
  - `cout<<" x["<<i<<" ]="<<x[i];`

# Vector methods

---

- |                                      |   |
|--------------------------------------|---|
| • <code>.at(index), [index]</code>   | returns the element                           |
| • <code>.push_back(value)</code>     | adds a value as last element                  |
| • <code>.pop_back()</code>           | removes last element                          |
| • <code>.size()</code>               | returns the size                              |
| • <code>.clear()</code>              | removes all elements                          |
| • <code>.empty()</code>              | returns true if vector is empty, false if not |
| • <code>.reverse()</code>            | reverse the order of elements                 |
| • <code>.resize(extra, value)</code> | adds extra new elements, all init with value  |
| • <code>.swap()</code>               | swap content of two vectors                   |

# Vectors VS Arrays

---

- ④ vectors are passed by value, while arrays are passed as references parameters to functions
  - vectors can be also passed as reference using "&"
- ④ with arrays its easy to read/write wrong memory address
  - vectors have some protection mechanism
- ④ vectors dynamically allocate more memory when need it
- ④ vectors are a class, so they have methods
- ④ whenever possible, use vectors for software development

# Searching and sorting Vectors

---

- ④ in principle, same algorithms like before
  - and more: max, min, median
- ④ implementation: by default vectors passed by value
  - therefore function-changes to argument does not reflect back to the call vector
  - solution: pass by reference
  - solution: use global variables
  - solution: use return values

# Basic hashing

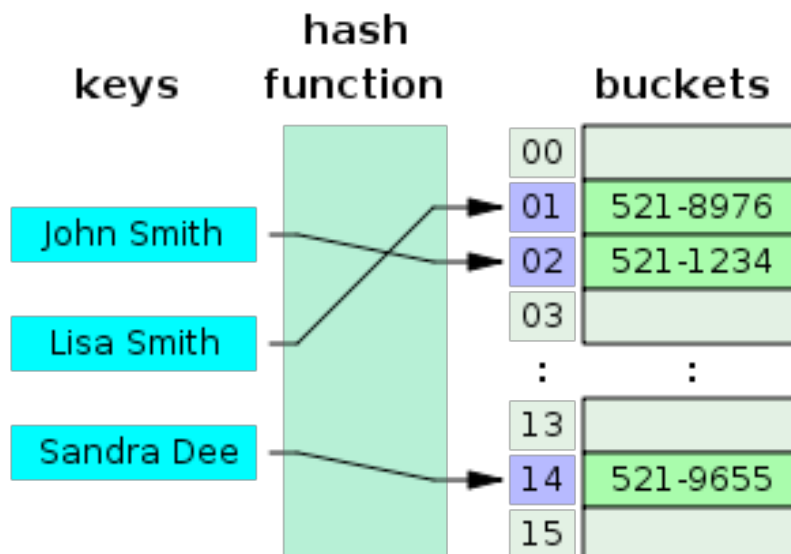

---

- ☉ arrays are very nice, but keys have to be integers
  - keys from 0 to N-1
- ☉ hash function: take input any key, returns an index (int)
- ☉ very useful when natural keys are not integers
  - names, words, addresses, phone numbers etc
  - even if key=integer (like phone #) they are not the integers we want as indices
- ☉ text processing : natural keys are words/n-grams/phrases
- ☉ databases: natural keys can be anything

# Hash Tables

---

- ☉ key -> index -> lookup in array / table

# Hash function: two qualities

---

- ④ `int hash_function (char[])`
- ④ quality ONE: one-to-one (injection). Different inputs result in different outputs
  - collision: having many words map to same index
  - collisions eventually will happen, need to be solved
  - collisions should be balanced (uniformly distributed) per output indices
- ④ quality TWO: the set of returned indices must be manageable
  - for example returns integers from 1 to 100000
  - or returns integers in range (0, MAXHASH)

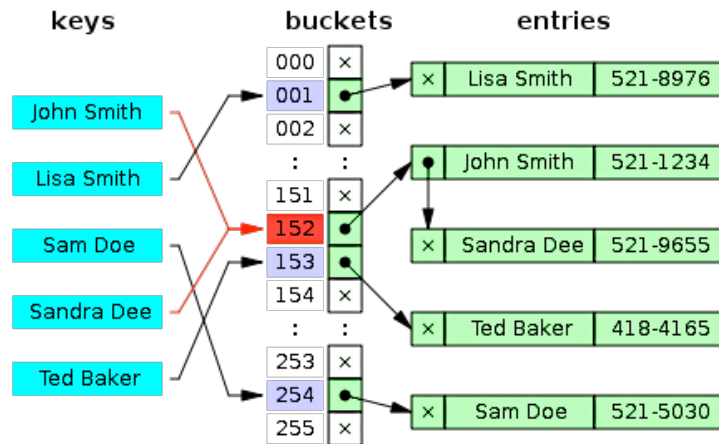

# Simple hash function

---

- ④ return a simple combination of characters, modulo MAXHASH
- ④ `int MAXHASH=100000;`
- ④ `int hash_function(char[ ]) // returns integers between 0 and MAXHASH`
  - `int sum=0,i=0;`
  - `while(char[i]>0) {sum+=char[i] * ++i*i;}`
  - `return sum % MAXHASH;`

# Hash Tables - Collisions

- when several keys (words) map to the same key (index)
- have to store the actual keys in a list
  - list head stored at the index
- key -> index -> list\_head -> search for that key

# Hash Tables - Collisions

- when several keys (words) map to the same key (index)
- have to store the actual keys in a list
  - list head stored at the index
- key -> index -> list\_head -> search for that key
